

Image Animation with Perturbed Masks

Yoav Shalev Lior Wolf
Tel Aviv University

Abstract

We present a novel approach for image-animation of a source image by a driving video, both depicting the same type of object. We do not assume the existence of pose models and our method is able to animate arbitrary objects without knowledge of the object’s structure. Furthermore, both the driving video and the source image are only seen during test-time. Our method is based on a shared mask generator, which separates the foreground object from its background, and captures the object’s general pose and shape. A mask-refinement module then replaces, in the mask extracted from the driver image, the identity of the driver with the identity of the source. Conditioned on the source image, the transformed mask is then decoded by a multi-scale generator that renders a realistic image, in which the content of the source frame is animated by the pose in the driving video. Due to lack of fully supervised data, we train on the task of reconstructing frames from the same video the source image is taken from. In order to control the source of the identity of the output frame, we employ during training perturbations that remove the unwanted identity information. Our method is shown to greatly outperform the state of the art methods on multiple benchmarks. Our code and samples are available at <https://github.com/itsyoavshalev/Image-Animation-with-Perturbed-Masks>.

1. Introduction

The ability to reanimate a still image based on a driving video has been extensively studied in recent years[17, 14, 11]. The developed methods achieve an increased degree of accuracy in both maintaining the source identity, as extracted from the source frame, and in replicating the motion pattern of the driver’s frame. In addition, the recent methods also show good generalization to unseen identities and are relatively robust and have fewer artifacts than the older methods. The relative ease in which these methods can be applied out-of-the-box has led to their adoption in various visual effects.

Interestingly, some of the most striking results have been

obtained with methods that are model-free, i.e., that do not rely, for example, on post-extraction models [10, 19, 9, 22, 15, 16]. This indicates that such methods can convincingly disentangle shape and identity from motion[12, 6].

There are, however, a few aspects in which such methods are still wanting. First, the generated videos are not without noticeable artifacts. Second, some of the identity from the source image is lost and replaced by identity elements from the driving video. Third, the animation of the generated video does not always match the motion in the driver video.

Here, we propose a method that is preferable to the existing work in terms of motion accuracy, identity and background preservation, and the quality of the generated video. Our method relies on a mask-based representation of the driving pose and on explicit conditioning on the source foreground mask. Both masks (source and driver) are extracted by the same network. The driver mask goes through an additional refinement stage that acts to replace the identity information in the mask.

The reliance on masks has many advantages. First, it eliminates many of the identity cues from the driving video. Second, it explicitly models the region that needs to be replaced in the source image. Third, it is common to both source and target, thus allowing, with proper augmentation, to train only on source videos. Fourth, it captures a detailed description of the object’s pose and shape.

Interestingly, unlike many of the previous methods, we do not rely on GANs [8] to generate proper outputs from combinations of different inputs. Instead, we employ an encoder-decoder in which the identity is manipulated in order to direct the networks toward employing specific parts of the information from each input. To summarize, our contributions are: (i) An image animation method that is based on applying a masking process to both the source image and the driving video; (ii) The method generalizes to unseen identities of the same type and is able to animate arbitrary objects better than previous work; (iii) The mask generator separates the foreground object from its background and captures, in a generic way, the fine details of the object’s pose and shape; (iv) Conditioning the mask of the driving frame on the source frame and its mask to introduce the identity of the source frame; (v) Employing perturbations

in order to remove the foreground identity of the driver’s frame from the mask; and (vi) A comprehensive evaluation of several different applications of our method, which show a sizable improvement over the current state of the art in image animation.

2. Related Work

Much of the work on image animation relies on prior information on the animated object, in the form of explicit modeling of the the object’s structure. For example, [24, 23] animate a source image using facial landmarks and [14] developed a human-pose-guided image generator. However, in many applications, an explicit model is not available. Our method is model-free and able to animate arbitrary objects.

There are many model-free contributions in the field of image to image translation, in which an input image from one domain is mapped to an analog image from another domain. [10] learn a map between two domains using a conditional GAN. [19] developed a multi-scale GAN that generates high-resolution images from semantic label maps. [9] encodes images of both domains into a shared content space and a domain-specific style space. Content code of one domain is combined with the style code of the other domain, and then the image is generated using a domain specific decoder. For this class of methods, the model is not able to generalize to other unseen domains of the same category without retraining. In contrast, for a given type of model (e.g. human faces), our method is trained once, and able to generalize to unseen domains of the same type (e.g. the source and driving faces can be of any identity).

More related to our method, [22] assume a reference frame for each video, and learn a dense motion field that maps pixels from a source frame to its reference frame, and another mapping from the reference frame to the driver’s frame. [15] extract landmarks for driving and source images of arbitrary objects, and generate motion heatmaps from the key-points displacements. The heatmaps and the source image are then processed in order to generate the final prediction. A follow-up work by [16] extracts a first order motion-representation, consisting of sparse key-points and local affine transformations, with respect to a reference frame. The motion representation is then processed to generate a dense motion field, from the driver’s frame to the source’s, and occlusion maps to mask out regions that should be inpainted by the generator. This method, like ours, does not employ GANs. The main differences are that our method does not assume a reference frame, instead of key-points, we generate objects masks, which are more informative regarding pose and shape, and our innovative use of perturbations.

Other methods, including [12, 6] learn a part-based disentangled representation of shape and appearance, and try to ensure that local changes in appearance and shape re-

main local, and do not affect the overall representation. Unlike these contributions, our method does not assume a pre-defined number of parts and by using the mask refinement module, it is able to better remove the driver’s identity and inject that of the source.

When a source video is available, video to video translation methods [3, 11] may be used for the task of motion transfer, by utilizing the rich appearance and pose information of the source video. Such methods learn a mapping between two domains and are able to generate realistic results, where the source video is animated by the driver video. These methods requires a large number of source frames at train time, and require a long training process for every target subject. In contrast, our model is able to animate a single source image, which is unseen during training, and employs a driving video with another novel person.

3. Method

The method consists of four encoder-decoder networks: the mask generator m , the mask refinement network r , the low resolution frame generator ℓ , and the high resolution frame generator h . The networks transform an input source frame s and a driving frame d into the generated high resolution frame f . This is done for each driving frame separately through the following process, as depicted in figure 1:

$$m_s = m(s) \quad (1)$$

$$m_d = r(\mathbf{D}(s), m_s, \mathbf{P}_{\text{test}}(m(d))) \quad (2)$$

$$c = \ell(\mathbf{D}(s), m_s, m_d) \quad (3)$$

$$f = h(s, \mathbf{U}(m_s), \mathbf{U}(m_d), c), \quad (4)$$

where m_s and m_d are the source mask and the driving refined mask respectively, \mathbf{P}_{test} is an identity-perturbation operator applied at test time, which sets to zero pixels that are smaller than a threshold ρ , and scales-down the mask by 25%, c is the coarse (low resolution) generated frame, and \mathbf{D} (\mathbf{U}) is a downscale (upscale) operator, implemented using a bi-linear interpolation, that transforms an image of resolution 256×256 to an image of resolution 64×64 (or vice versa). For each driver’s mask, we set the threshold ρ in \mathbf{P}_{test} to be the median pixel value.

The goal of this process is to generate a frame f that contains the foreground and background of the source frame s , such that the pose of the foreground object in s is modified to match that of the driver frame d .

The generated frame is being synthesized in a hierarchical process in which the coarse frame c is first generated using ℓ and is then refined by the network h . Both generators (ℓ and h) utilize the mask m_s to attend the foreground and background objects in the source frame and to infer the occluded regions that need to be generated.

The driver’s mask m_d is the only conditioning on the frame generation process that stems from the driver’s frame

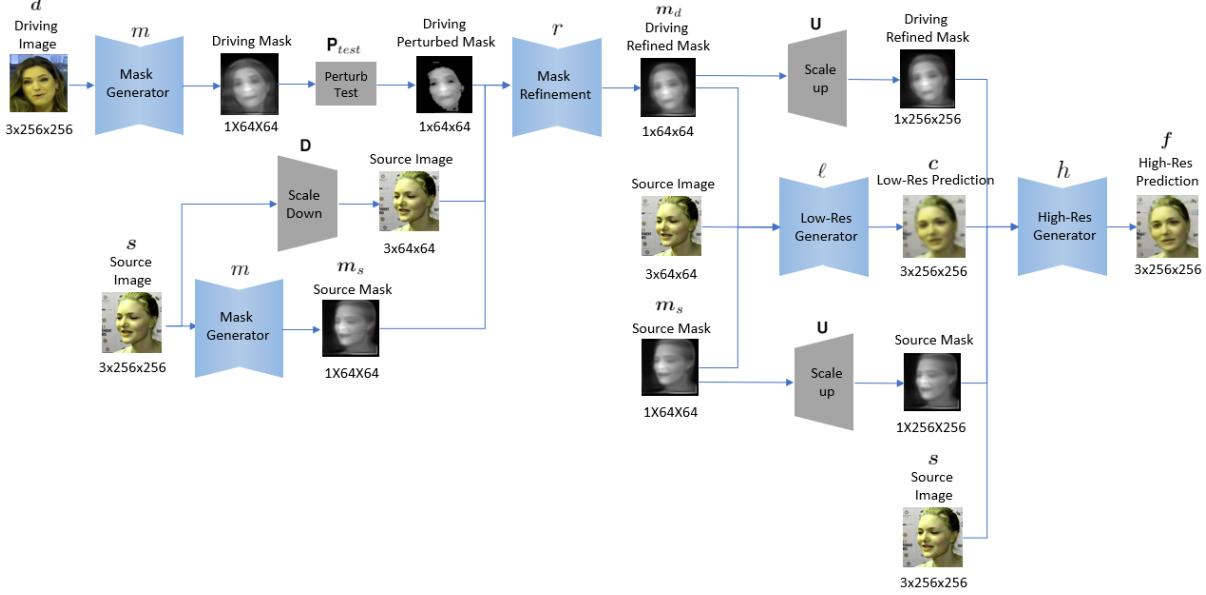

Figure 1. Overview of our method at test time. Source and driving masks m_s and $m(d)$ are generated using the mask generator m . The identity-perturbation operator \mathbf{P}_{test} is then applied to the driver’s mask, and along with a scaled-down version of the source’s image $\mathbf{D}(s)$ and the source’s mask m_s , they are fed into the mask refinement network r , in order to generate the driver’s refined mask m_d . Next, the refined mask m_d , the source’s mask m_s and the scaled-down source’s image $\mathbf{D}(s)$ are fed into the low-res generator ℓ , which generate the initial prediction c . Finally, the scaled-up refined mask $\mathbf{U}(m_d)$, the source image s , the initial prediction c and the scaled-up source’s mask $\mathbf{U}(m_s)$ are fed into the high-res generator h , in order to generate the final prediction f .

d. It, therefore, needs to encode the pose of the foreground object in the driving frame. However, this has to be done in a way that is invariant to the identity of this foreground object. For example, when reanimating person A based on a driver video of person B, the pose of B should be given, while discarding the body shape information of B. Otherwise, the generated frame could have the appearance of the source’s foreground and a body shape that mixes that of the person in the source frame and that of the person in the driving frame.

The roles of the identity perturbation operator \mathbf{P}_{test} , and of the refinement network r , is to remove the foreground identity of the driver’s frame from the mask, and install the identity of the foreground of the source frame. At test time, the source and driving frames are of different identities and the inputs to the network ℓ are the source frame, the source mask and the refined mask of the driver frame. Finally, the coarse generated frame is enhanced by the network h .

Architecture Following [16], the mask generator m , the mask refinement network r and the high-res generator h have the same encoder-decoder architecture, followed by a $conv_{7 \times 7}$ layer and a *sigmoid* activation. The encoder (decoder) consists of five encoding (decoding) blocks, where each encoding block is a sequence of $conv_{3 \times 3} - relu - batch_norm - avg_pool_{2 \times 2}$, and each decoding block is a sequence of $up_sample_{2 \times 2} - conv_{3 \times 3} - batch_norm - relu$. Only for the high-res generator h we add skip connec-

tions from each of the encoding layers, to its corresponding decoding layer, to form a U-Net architecture.

The encoder of the low-res generator ℓ consists of $conv_{7 \times 7} - batch_norm - relu$, followed by six residual blocks, each block consisting of $batch_norm - relu - conv_{3 \times 3} - batch_norm - relu - conv_{3 \times 3}$. The decoder consists of two blocks, each is a sequence of $up_sample_{2 \times 2} - conv_{3 \times 3} - batch_norm - relu$. The decoder is followed by a $conv_{7 \times 7}$ layer and a *sigmoid* activation.

3.1. Training

The training is being performed using source videos only, i.e., the driving- and source-frame are taken from the same video. The underlying reason is that for the type of supervised loss terms we use, a ground-truth target frame is required. The main challenge is, therefore, to train networks that are robust enough for accepting a driving frame d that is from another video.

As shown in Fig. 2, training involves a slightly modified pipeline, in which an augmentation \mathbf{A} is applied to the driving image d , and a much more elaborate perturbation \mathbf{P}_{train} takes place. Additionally, the low-res and high-res generators ℓ and h are using the driver’s mask $m(\mathbf{A}(d))$ and its up-scaled version $\mathbf{U}(m(\mathbf{A}(d)))$ respectively, instead of using the refined mask m_d :

$$m_d = r(\mathbf{D}(s), m_s, \mathbf{P}_{train}(m(\mathbf{A}(d)))) \quad (5)$$

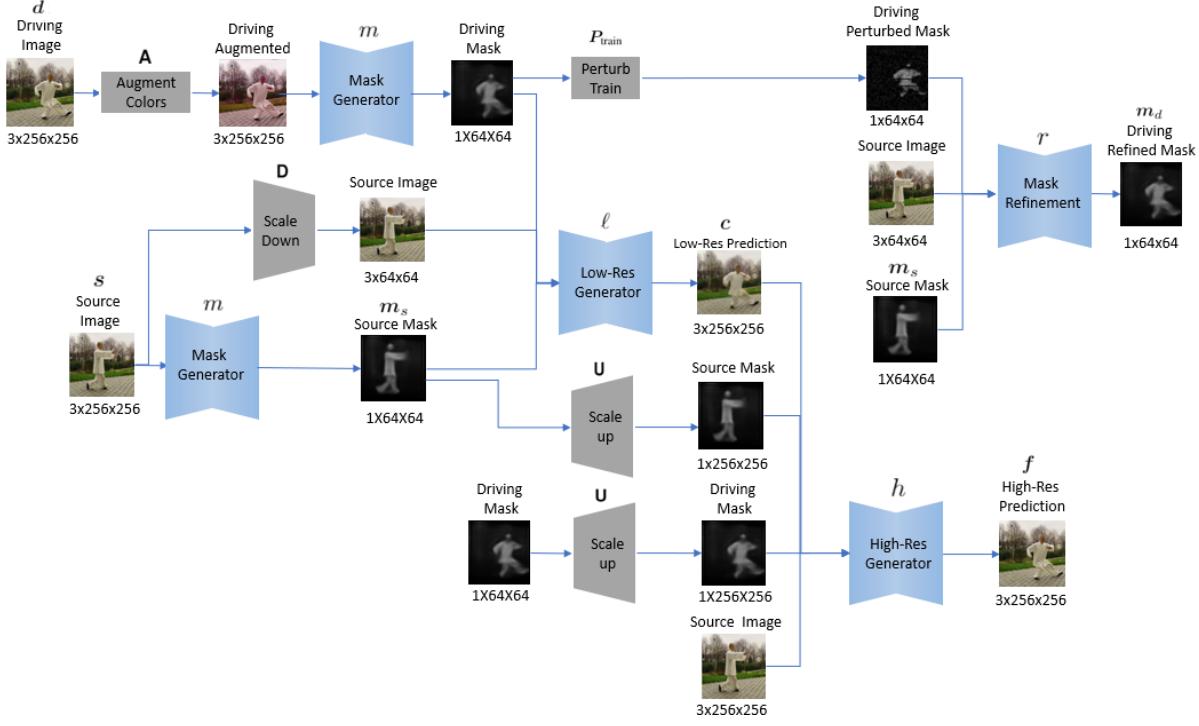

Figure 2. The method at train time. The driving image d is augmented using **A**. We generate the driver’s refined mask m_d as in test time, except that the operator P_{train} is applied instead of P_{test} . Instead of getting the driver’s refined mask m_d as in test time, the low-res and high-res generators ℓ and h are using the driver’s mask $m(\mathbf{A}(d))$ and its up-scaled version $\mathbf{U}(m(\mathbf{A}(d)))$, respectively.

$$c = \ell(\mathbf{D}(s), m_s, m(\mathbf{A}(d))) \quad (6)$$

$$f = h(s, \mathbf{U}(m_s), \mathbf{U}(m(\mathbf{A}(d))), c), \quad (7)$$

The augmentation **A** is a color transformation that scales the input’s brightness, contrast and saturation by a random value drawn from [0.9, 1.1], and shifts its hue by a random value drawn from [-0.1, 0.1]. The goal of this augmentation is to encourage the generated masks to be invariant to the input’s appearance despite the challenge mentioned above of training on frames from the same video.

P_{train} performs the following steps sequentially: (i) breaks the image vertically (horizontally) into six parts, and scales each part horizontally (vertically) by a random value drawn from [0.75, 1.25]. Next, it scales the entire output vertically (horizontally), by a random value drawn from [0.75, 1.25]. (ii) similarly to P_{test} , setting to zero pixels that are lower than the threshold value ρ , and, finally (iii) adds an element-wise noise sampled from the Poisson distributions with $\lambda = 20$. All hyper-parameters values, including these constants, were selected using a cross-validation on the training set of the Tai-Chi [16] dataset and fixed throughout all experiments on all benchmarks.

Loss Terms We train our system end to end using only two loss terms: a mask refinement loss and a perceptual reconstruction loss. At train time, the role of the mask refinement network r is to recover the driver’s identity after

it was reduced by the perturbation operator P_{train} , therefore, we minimize the L_1 loss of the driver’s mask $m(\mathbf{A}(d))$ and its refined mask m_d :

$$\mathcal{L}_{\text{mask}}(d) = L_1(m_d, m(\mathbf{A}(d))). \quad (8)$$

For the image reconstruction loss of the generators ℓ and h , following [16] and based on the implementation of [18], we minimize a perceptual loss using the pre-trained weights of a VGG-19 model. For two images a and b , the reconstruction loss terms using the j^{th} layer of the pre-trained VGG model are written as:

$$\mathcal{L}_{\text{VGG}}(a, b)_j = \text{AVG}(|\mathbf{N}_j(a) - \mathbf{N}_j(b)|) \quad (9)$$

where AVG is the average operator and $\mathbf{N}_j(\cdot)$ are the features extracted using the j^{th} -layer of the pre-trained VGG model. For the coarse and fine predictions c and f , and a driving frame d , we compute the following reconstruction loss for multiple resolutions:

$$\mathcal{L}_{\text{reconstruct}} = \sum_s \sum_j \mathcal{L}_{\text{VGG}}(c_s, d_s)_j + \mathcal{L}_{\text{VGG}}(f_s, d_s)_j$$

where input image a_s , has a resolution $s \in [256^2, 128^2, 64^2]$. We use the first, the third and the fifth ReLU layers of the VGG-19 model. Note that while the VGG network was designed for a specific resolution

(224^2) , the first layers are fully convolutional, and can be used for an arbitrary input scale.

The combined loss is given by $\mathcal{L} = \lambda_1 \mathcal{L}_{\text{mask}} + \lambda_2 \mathcal{L}_{\text{reconstruct}}$, for weight parameters $\lambda_1 = 100$ and $\lambda_2 = 10$. To avoid unwanted adaptation of the network m , the back-propagation of $\mathcal{L}_{\text{mask}}$ only updates the weights of the mask refinement network r . When backpropagating the second part of the reconstruction loss $\sum_s \sum_j \mathcal{L}_{\text{VGG}}(\mathbf{f}_s, \mathbf{d}_s)_j$, only the top-scale generator h is updated. The Adam optimizer is employed with a learning rate of 2×10^{-4} and β values of 0.5 and 0.9. The batch size is 16. Following [16], we decay the learning rate at epochs 60 and 90, running for a total of 100 epochs. The mask refinement network r starts training after we complete the first training epoch, when the outputs of the mask generator m start to be meaningful.

4. Experiments

The training and evaluation were done using three different datasets, containing short videos of diverse objects. **Tai-Chi-HD** is a dataset containing short videos of people doing tai-chi exercises. Following [16], 3,141 tai-chi videos were downloaded from YouTube. The videos were cropped and resized to a resolution of 256^2 , while preserving the aspect ratio. There are 3,016 training videos and 125 test videos. **VoxCeleb** is an audio-visual dataset consisting of short videos of talking faces, introduced by [13]. Vox-Celeb1 is the collection used, and as pre-processing, bounding boxes of the faces were extracted and resized to 256^2 , while preserving the aspect ratio. It contains an overall number of 18,556 training videos and 485 test videos. The **BAIR** dataset contains short videos of Sawyer robotic arms interacting with different objects [7]. It contains 42,880 training videos and 128 test videos. Each video consists of 30 frames and has a resolution of 256^2 . We were unable to obtain the UvA-NEMO smile dataset of [5], which was utilized in some of the earlier contributions.

We follow the evaluation process of [16]. First, the method is quantitatively evaluated for video reconstruction, and then qualitatively for the task of image animation, where the source and driving videos are of different identities. Additionally, despite being model-free, we compare to model-based methods in the few-shot-learning scenario. In this case, our method, unlike the baseline methods, does not employ any few shot samples.

The metrics are borrowed from related work: **L1** is the L1 distance between the generated and ground-truth videos. **Average Key-points Distance (AKD)** measures the average distance between the key-points of the generated and ground-truth videos. For the Tai-Chi-HD dataset, we use the human-pose estimator of [2], and for the VoxCeleb dataset we use the facial landmark detector of [1]. **Missing Key-points Rate (MKR)** measures the percentage of key-points that were successfully detected in the ground-truth video,

but were missing in the generated video. The human-pose estimator of [2] outputs for every keypoint an indicator of whether it was successfully detected. Using this indicator, we measure MKR for the Tai-Chi-HD dataset. **Average Euclidean Distance (AED)** measures the average Euclidean distance in some embedding space between the representations of the ground-truth and generated videos. Following [16], we employ the feature embedding of [15]. **Structural Similarity (SSIM) [21]**: we compare the structural similarity of the ground-truth and generated images. **Cosine Similarity (CSIM)**: we measure the identity similarity of the generated and ground-truth faces, by comparing the cosine similarity of embedding vectors generated by a face recognition network [4].

4.1. Video Reconstruction

The video reconstruction benchmarks follow the training procedure in that the source and target frames are taken from the same video. For evaluation, the first frame of a test video is used as the source frame and the remaining frames of the same video as the driving frames. The goal is to reconstruct all frames of the test video, except the first.

L1, AKD, MKR and AED are compared with the state of the art model-free methods, including X2Face of [22], MonkeyNet of [15] and the method suggested by [16], which we refer to as FOMM. The results are reported in Tab. 1. Evidently, our method outperforms the baselines for each of the datasets and all metrics by a significant margin, except for the AKD measure on the VoxCeleb dataset, where accuracy was decreased by 2.7%. The most significant improvement is for the Tai-Chi-HD dataset, which is the most challenging dataset, because it consists of diverse movements of a highly non-rigid type.

Next, we follow [24] and compare SSIM and CSIM with X2Face, Pix2PixHD [20] and the FSAL method [24]. The baselines are evaluated in the few-shot-learning setting, where models are fine-tuned on a set of size #FT, consisting of frames of a person that was not seen during the initial meta-learning step. After the fine-tuning step, the evaluation is done on a hold-out set, consisting of unseen frames of the same person. The evaluation is done for VoxCeleb1 and the results are reported in Tab. 2. As can be seen, our method generalizes better and outperforms the baselines in SSIM and even more so in CSIM. This is especially indicative of the method’s capabilities, since (i) we skip the fine-tuning step for our model (in our case #FT = 0), and (ii) X2Face and FSAL were designed specifically for faces, while our method is model-free and generic.

4.2. Image Animation

The task of image animation is to animate a source image using a driving video. The object (and its background) in the source and driving inputs may have different identi-

Method	Tai-Chi-HD				VoxCeleb			BAIR
	L1	AKD	MKR	AED	L1	AKD	AED	L1
X2Face	0.080	17.654	0.109	0.272	0.078	7.687	0.405	0.065
Monkey-Net	0.077	10.798	0.059	0.228	0.049	1.878	0.199	0.034
FOMM	0.063	6.862	0.036	0.179	0.043	1.294	0.140	0.027
Ours	0.047	4.239	0.015	0.147	0.034	1.329	0.130	0.021
Improvement	25.4%	38.2%	58.3%	17.9%	20.9%	-2.7%	7.1%	22.2%

Table 1. Video reconstruction results (lower is better). Improvement is relative to FOMM.

ties and appearances. To this end, we use the first frame of a source video as the source frame for encoding the appearance, and we use all frames of the driving video as the driving frames for encoding the object’s motion. A video is generated where the content of the source frame is animated by the driving video.

Sample results for image animation compared to the baseline methods are shown in Fig. 4. For VoxCeleb, our method better preserves the identity of the source, and the facial expressions of the generated frames are more compatible with that of the driver’s. For the Tai-Chi-HD dataset, the baseline methods tend to generate infeasible poses for the fourth generated frame, while we do not. Unlike FOMM, we well maintain environment elements, such as the stick on the top-right of the generated frame. For the BAIR dataset, the images generated by our method are the sharpest, and it is the only method that places the generated object in the right position. Note that the samples were selected to match those of [15], and not by us.

4.3. Ablation

The main challenge in reanimation is to replace the identity on the driver’s mask to that of the source, while keeping on driver’s general pose and shape. We do that in two steps: (i) the driver’s identity is reduced by applying \mathbf{P}_{test} , (ii) we inject the source’s identity using the mask refinement network r . To evaluate the roles of \mathbf{P}_{test} and r , we evaluate three reduced methods: no_pert, no_ref and no_id, where the first, second, or both steps are removed, respectively.

Ablation and intermediate results generated by our pipeline are shown in Fig. 3. As can be seen, the generated masks m_s and $m(d)$ capture very accurately the object’s pose and shape, and the mask refinement network r successfully applies the source’s identity to the driver’s mask. Comparing the generated frame f to that of FOMM, we notice that for the Tai-Chi-HD dataset, the pose of the generated body using our method, is much more compatible with that of the driver’s, where the model of FOMM generates a distorted body. For the VoxCeleb dataset, using our method, the identity of the source is better preserved, as it also reveals a small portion of the teeth, as the driver does. For

the BAIR dataset, unlike FOMM, our method was able to inpaint the occluded surface, including the white and blue items on the right of the generated frame.

Examining the generated frames of the ablation models shows that both steps, identity-perturbation and mask refinement, are critical for our image-animation pipeline. The frames generated by no_pert and no_id have significant traces of the driver’s identity. This is especially clear for VoxCeleb, on the forehead area of no_pert and the general appearance for no_id. Similarly, for the Tai-Chi-HD dataset, the frame generated by no_ref contains traces from the driver’s environment, and for the other datasets it generates distorted results.

4.4. User study

To qualitatively evaluate our method and compare with existing work, we presented volunteers with a source image, a driving video, and four randomly ordered generated videos, one for each baseline method. They were asked to (i) select the most realistic animation of the source image, and (ii) select the video with the highest fidelity to the driver video. For each of the $n = 25$ participants, we repeated the experiment three times, each time using a different dataset and a random test sample.

The results are reported in Tab. 3 and are highly consistent with the video reconstruction results, indicating that the quality and the animation of the videos generated by our method contain fewer artifacts and are better synchronized with the driver videos.

5. Conclusions

A novel method for conditionally reanimating a frame is presented. It utilizes a masking mechanism as a means for encoding pose information. By properly augmenting and refining the masks, we are able to effectively extract both the source and the driving masks, while accurately capturing the shape and foreground/background separation of the first, and recovering an identity-free pose from the latter. Our results outperform the state of the art by a sizable margin on the available benchmarks.

Method	#FT	SSIM \uparrow	CSIM \uparrow
X2Face	1/8/32	0.68/0.73/0.75	0.16/0.17/0.18
P2PHD	1/8/32	0.56/0.64/0.70	0.09/0.12/0.16
FSAL	1/8/32	0.67/0.71/0.74	0.15/0.17/0.19
Ours	0	0.80	0.70

Table 2. Results on VoxCeleb1 in the few-shot learning scenario. Unlike the other methods, we do not perform fine-tuning on the identity in the source image. #FT=number of images used for fine-tuning. P2PHD=Pix2PixHD.

	Dataset	X2Face	MN	FOMM	Ours
Quality	<i>Tai-Chi-HD</i>	0%	4%	16%	80%
	<i>VoxCeleb</i>	0%	8%	16%	76%
